PREFACE

This document, FJSRL-TR-80-0015, summarizes computer calculations (MNDO) of heats of formations and resultant specific impulse data on formulations including energetic plasticizers. This work was done under Work Unit 2303-F3-01 and was not previously published by the authors.

I. INTRODUCTION

Composite energetic materials (explosives and propellants) in use today are composed of approximately 80-85% energetic materials and 15-20% low energy materials. These low energy materials are generally comprised of 10-15% plasticizer and other additives. In order to improve the energy content of such composites, work is being done to increase the energy content of the low energy materials fraction.

Recent work at the Seiler Laboratory and Los Alamos Scientific Laboratory (LASL) resulted in the development of a new class of polynitroethyl-vinylether polymers. Dinitropropylvinylether polymer (DMFVEP), shown in Figure 1, was found to have excellent thermal (DTA = 220°C, emo.), physical and chemical properties. The incorporation of such energetic binder (polymer) ingredients into solid propellant and explosive formulations is an excellent concept for increasing the energy output during the combustion and detonation processes. Subsequent work on DNFVEP revealed a critical lack of available plasticizers that would plasticize this energetic binder². Two energetic plasticizers available, FEFO (Figure 1) and nitroglycerin (NG), suffer from thermal stability and sensitivity problems for applications at the higher operating temperatures projected for future systems. Thus, synthesis of a new class of energetic plasticizers was initiated at this laboratory.

This new class of energetic plasticizers was modeled after the structural features present in the energetic binder DNPVEP. These bis-fluorodinitro-ethyl alkyl ethers (FEME, Figure 1) have very similar chemical functionalities to the DNPVEP including ether linkages and polynitroethyl side chains. During the synthesis of examples of this class³, we decided to investigate

calculated energy content improvements in formulations utilizing the energetic plasticizers compared to formulations using non-energetic plasticizers. In addition to the carbon chain examples, various potential energetic plasticizers, heteroatoms and nitro substituents were investigated.

II. CALCULATIONAL PROCEDURES

Experimental heats of formation are not available for the FEME series of plasticizers, so the MNDO molecular orbital computer program developed by M. J. S. Dewar at the University of Texas was used to calculate heats of formation for the various plasticizers. The calculation was performed with complete geometry optimization of the molecule. Previous calculations with MNDO have shown that for molecules of this size, the calculated heat of formation is usually too high. However, actual trends among the various plasticizers should be reproduced well by the calculated heats of formation.

The heat of formation is used along with the density and chemical composition as input to the performance program ISP⁵. This program calculates an equilibrium isentropic expansion from the rocket motor chamber to any arbitrary exit pressure. The Isp's calculated in this report were those for the expansion to sea level, 14.696 psia, Compositions of the propellant with and without the energetic plasticizers were used as input in order to make performance comparisons. These compositions were varied to achieve maximum Isp, but were kept within reasonable bounds for a standard aluminized solid propellant⁶. Densities of the energetic plasticizers were assumed to be the same as that of FEFO, 1.595g/cc.

III. RESULTS

Table I gives the calculated heats of formation for the various plasticizers. Included for comparison is a second theoretical value for FEFO

apparently based on a group-addivity calculation⁶. The group additivity scheme will probably produce a heat of formation lower than the true one since it does not take into account destabilizing steric interference which will be present among the nitro groups. Thus the true heat of formation probably lies between the MNDO result and the group additivity result.

Because of uncertainty in the heat of formation, a sensitivity study was performed in order to calculate its effect on the predicted performance. Table II, which gives the calculated performances of the various plasticizer compositions based on derivatives of FEME-3, shows that there is a difference of about 2.5 sec in the Isp between the two different heats of formation for FEME-3. One heat of formation is the MNDO-calculated number, and the other is the group additivity estimated one for FEFO. (The two extra methylene groups make little difference in the heat of formation.) Thus the best value for Isp probably lies between the two given in the table.

Figure 2 shows the trend in predicted performance as the number of methylene groups in the plasticizer increases. Note that there is a slow decrease of about 0.2 sec/methylene group. These calculations are based on the group additivity calculated heats of formation and may, therefore, be somewhat pessimistic. It is obvious, however, that the predicted performances for the energetic plasticizer formulations are several seconds higher than the standard non-energetic formulation and approach the performance given by using nitroglycerin as a plasticizer (See Table III for these compositions).

Table III gives the compositions used to achieve the best Isp's shown in the previous table and Figure 2. Recall that these compositions were kept within reasonable bounds for an aluminized solid propellant. The compositions which give the best Isp are identical for all of the FEME-3 derivatives, and vary in a regular fashion as the number of methylene groups increase. Note the large differences in composition between the standard propellant composition and the energetic plasticizer combinations.

IV. CONCLUSIONS

The Isp calculations indicate that these energetic plasticizers have promise as useful additives to propellant and explosive formulations. The results reveal a trend toward decreasing Isp values as the hydrocarbon chain increases. The improvement in calculated Isp values (4-6 seconds) over non-energetic plasticizer formulations are high enough that these energetic plasticizers should warrant serious consideration for future applications. In addition, if an energetic binder were included in the formulations used in these calculations the total improvement in specific impulse would probably be on the order of 6-8 seconds.

It is important to note that these calculations were not totally optimized for formulation composition, but were based on reasonable estimates.

Also, it should be noted that the ISP program assumes ideal combustion and expansion, and, thus non-ideal combustion or expansion could change the results somewhat.

However, these results are deinitely encouraging and the Isp technique should be used as a guide for the synthesis of other potential energetic plasticizers. To verify these calculated improvements, experimental work on actual formulations and measured performance should be done.
